

(a) Exactly 0.0000, twice.
My prediction was wrong.

(b) Cost appears only when
the column has splittable values

What this fixes

Note 641 wrote:

"each column costs rho 0.02-0.025
in a thin domain"

That is true only for columns that
CARRY VALUES. A constant column with
mask 0 is never a split candidate, so
the tree ignores it entirely.

Consequence: a partial-coverage axis
does NOT pay for the domains it does
not cover. Budget only the rows that
actually have values.

Here: 310 rows carry values, and the
shuffled arm shows those 310 rows cost
-0.0048 of board through overfitting.
